

Wrong Place, Wrong Time: The Long-Run Effects of In-Utero Exposure to Malaria on Educational Attainment*

Henrique Veras de Paiva Fonseca[†]
Job Market Paper

This Version: October 6, 2020

Abstract

This paper investigates the long-term relationship between early life exposure to malaria and human capital accumulation in Brazil. The identification strategy relies on exogenous variation in the risk of malaria outbreaks in different states and seasons of the year to identify in utero exposure according to the timing and location of birth. I find consistent negative treatment effects of in utero exposure to malaria on educational attainment. The effects are stronger for exposure during the first trimester of pregnancy than during other periods of gestation. Effective anti-malaria policies can, thus, be an important factor contributing to reducing the educational inequality by targeting pregnant women, especially those in their first months of gestation.

I Introduction

Malaria is a vector-borne disease with distribution and prevalence depending, to a certain extent, on geographic and environmental conditions. It is disproportionately concentrated in humid and tropical climate locations, wherein approximately half of the world population is at risk (WHO 2019). Malaria infections destroy red blood cells, depriving the distribution of oxygen and nutrients to the body tissue. The long-lasting consequences to health and cognitive development, however, are most powerful when exposure occurs during the first periods of life, whereby fetal development is hampered, leading to long-lasting consequences to cognition (Barreca 2010). Understanding such relationships and estimating the impacts of differential exposure to malaria on socioeconomic conditions are of extreme relevance to devise effective antimalarial interventions by identifying and targeting the most vulnerable population groups.

Estimating the long-term impact of changes in early life health distribution can be challenging because of omitted factors, such as unobserved underlying socioeconomic conditions, that might confound the results. Previous studies have addressed long-term socioeconomic consequences of malaria exposure by making use of exogenous declines in malaria rates after eradication campaigns or by exploring relationships between malaria transmission and climatic conditions across different geographic locations and years. These studies, however, do not fully account for predetermined unobserved heterogeneity across units of observation by identifying the degree of exposure based on regional differences in malaria intensity alone. The geographic distribution of malaria is endogenous to regional (potentially unobservable) characteristics, including local-level state capacity as well as community- and individual-level attributes that might contribute to the success or failure in efforts to controlling the disease.

To answer whether in utero exposure to malaria affects human capital accumulation, accounting for the potential regional endogeneity in malaria burden, this paper relies on two main sources of exogenous variations in its transmission rates in Brazil that jointly identify

the extent of the exposure during early life. The first is given by differential transmission risks across months and states, which determine heterogeneous levels of exposure across individuals within birth cohorts. Identifying exposure according to both location and month of birth serves a dual purpose for my analysis: first, it allows me to control for any unobserved regional effects, such as national policies that might heterogeneously affect individuals according to geographic location; second, I can ascertain the timing of individual-level exposure according to different periods of gestation, which allows me to test for heterogeneous treatment effects along the in utero life.

The second source of variation is represented by the sharp decline in the overall scale of malaria transmission due to the eradication efforts during the 1950s. This abrupt and arguably exogenous variation in the overall malaria transmission rates in Brazil provides a unique opportunity to estimate the magnitude of the average effect of in utero exposure to malaria among individuals born around that period because Brazil underwent a sharp and almost instantaneous decline in malaria rates after the eradication campaign efforts, with the application of DDT spraying inside houses and anti-malarial drugs distribution.¹ This paper, thus, sheds light on the potential role of directed efforts to fight malaria in endemic areas by identifying the critical periods of in utero exposure and their consequences for economic outcomes.²

I find consistently negative effects of early life exposure to malaria on educational attainment for individuals born shortly before the eradication. On average, an increase in the in utero exposure to malaria from the fifth to the ninety-fifth percentile of the transmission probability distribution reduces educational attainment by nearly 0.17 years and leads to reductions of approximately 1.59 percentage points in the probability of primary completion and 2.16 percentage points in the probability of secondary completion.

1. An important attribute of the worldwide campaign is that its enactment was possible after the discovery of the insecticidal properties of DDT, and therefore, alleviates concerns about the exogeneity of the campaign to the outcome variables analyzed.

2. Epidemiological studies have also addressed the consequences of different timing of malaria infection during pregnancy. However, these studies do not fully account for confounding factors and the small sample sizes that frequently are used make it difficult to generalize the findings.

In the subsequent analysis, I consider different critical periods of early life exposure – according to trimesters of pregnancy – to test for heterogeneous treatment effects during different periods of exposure. Conceptually, the timing of malaria infection might lead to different patterns of subsequent health conditions. Early gestational malaria, occurring within the first 18 weeks following conception, is associated with symmetric growth retardation, thereby causing permanent neurological consequences for the infant.³ However, asymmetric growth retardations, which are associated with infections at later stages, may also lead to ill effects, such as low birth weight, increasing the likelihood of long-term repercussions. Some studies, for example, point out to the relatively higher risk of malaria infection during the second trimester of pregnancy, a critical period of gestation (Singh, Shukla, and Sharma 1999; Desai, Ter Kuile, Nosten, McGready, Asamoah, Brabin, and Newman 2007). Additionally, Luxemburger, McGready, Kham, Morison, Cho, Chongsuphajaisiddhi, White, and Nosten (2001) find low birth weight, and other sequelae, after infections during the third trimester of pregnancy. The research design followed by this paper, thus, remains agnostic as to what are the most critical periods of exposure to malaria and explores the long-term effects on a range of different early life periods. The results of this analysis indicate heterogeneous treatment effects according to the timing of exposure, with the largest effects stemming from exposure to the disease during the first months of intrauterine life.

This paper broadly relates to the empirical literature of long-term effects of early life environmental shocks on health and socioeconomic outcomes. The “fetal origins hypothesis”, proposed by this strand of the epidemiological and economic literature, assesses the relative importance of the persistence of in-utero conditions to subsequent health and mortality (Almond and Currie 2011). This hypothesis suggests that environmental shocks on health are most powerful during the early periods of life, when the organs and body systems are

3. Epidemiological studies have found severe consequences for later-life health after deterioration of initial health stock. Ravelli, Stein, and Susser (1976) found that exposure to famine on the first trimester of pregnancy leads to large effects on obesity rates after reaching adulthood. Moreover, McAlister (2007) has found long-term defects such as heart disease and deafness after pregnant women being infected with Rubella during the first trimester.

not fully developed. In his seminal study, Barker (1998) finds a strictly negative correlation between fetal nutrition and later-life mortality caused by heart disease, by linking health conditions in different locations in Britain from the 1901–1910 period to adult mortality in these locations between 1968 and 1978. Other studies have also found strong statistical associations between early-life conditions and long-term outcomes (Costa 2000, 2003; Costa and Lahey 2005; Hack, Flannery, Schluchter, Cartar, Borawski, and Klein 2002; Case, Fertig, and Paxson 2005; Black, Devereux, and Salvanes 2007; Currie and Moretti 2007), while others have incorporated robust empirical strategies by identifying exogenous shocks to the early life environment, including the Dutch “Hunger Winter” of 1944 (Stein, Susser, Saenger, and Marolla 1975; Roseboom, Painter, Abeelen, Veenendaal, and Rooij 2011), the 1918 Influenza Pandemic (Almond 2006; Almond and Mazumder 2005), the Chinese Great Famine (Chen and Zhou 2007; Meng and Qian 2009), and observation of Ramadan among Islamic religious groups (Almond and Mazumder 2011; Van Ewijk 2011).⁴

This paper is more closely connected to the literature exploring the potential negative effects of early life disease environment. Exposure to infectious diseases, in general, may affect fetal development, given that maternal energy might be diverged from the fetus to combat spread of disease (Almond and Currie 2011). Costa and Lahey (2005) explore quarter of birth variation as a proxy for early life environment in order to identify the effects of exposure to seasonal infectious diseases on mortality rates. Relying on historical records of malarial fevers among U.S soldiers across the country, combined with environmental factors that determine malaria prevalence, Hong (2007) finds that early life exposure to malaria is associated with lower health among Union Army soldiers during the 1850s. Barreca (2010) and Burlando (2015) find effects of malaria transmission in United States and Ethiopia, respectively, on schooling attainment by instrumenting malaria transmission with geographic factors such as temperature, rainfall, and topography. Rawlings (2016) identifies selection effects from in utero exposure to epidemic malaria in two states in Brazil. This paper adds to

4. Currie and Vogl (2013) provide a thorough review of the empirical evidence for the “fetal origins hypothesis” in the developing economies context.

this literature by identifying the critical exposure timing during early life: the first trimester of gestation.

This paper is also related to some other studies that have explored exogenous effects of eradication efforts to reduce different epidemic diseases – such as hookworm and malaria – to test whether larger gains in socioeconomic outcomes occurred among cohorts born in formerly more endemic locations than those in lower endemic areas before and after the eradication. Using this methodology, Bleakley (2007) found evidence of increases in school enrollment, attendance, and literacy rates following the successful eradication of hookworm disease in the American South, whereas other studies such as Lucas (2010), Cutler et al. (2010), and Bleakley (2010b), find positive effects of malaria eradication on human capital accumulation and other adult outcomes. Other studies have analyzed the effects of exposure to malaria on a range of different outcomes. For example, Venkataramani (2012) uses the Mexican eradication effort to estimate the impact of the malaria reduction on cognition in adults. Klejnstrup et al. (2018) use district-level variation in malaria rates together with declining overall transmission in Tanzania to estimate the effect of early-life exposure to malaria on children’s test scores for cognitive skills. None of these studies, however, explores seasonal variations in malaria transmission to identify the impact of the timing of birth on long-term outcomes. Additionally, the estimation strategy pursued by these studies might not adequately control for potential unobserved geographic heterogeneity in treated units. This paper takes a step further to cleanly identify exposure in a more granular manner by comparing heterogeneous exposure of individuals within the same location and year of birth.

The paper is structured in five sections, including this introduction, as follows: Section II presents some background information about malaria transmission and the history of malaria in Brazil. Section III details the data and some conceptual definitions as well as the research design implemented in this paper. Section IV exposes the main results, and further expands the analysis to exploit the long-run effects on other socioeconomic outcomes as well as potential heterogeneity associated with exposure. Section V concludes.

II Background

A Biological Aspects of the Disease

The malaria parasite is a micro-organism that belongs to the genus *Plasmodium*. The natural ecology of malaria involves the successive infection of humans and a vector, the female *Anopheles* mosquito.⁵ In humans, the parasites initially affect liver cells, subsequently spreading to the red blood cells. In this stage, the symptoms of the infection start to develop.⁶ Blood stage parasites in a form named *gametocytes* are responsible for the parasite's growth and multiplication when present on the blood meal taken from the *Anopheles* mosquito. The infected adult female mosquito, then, lays eggs in stagnant water reservoirs. The development of the eggs into larvae, then pupae, to reach adulthood is aquatic and takes approximately 9-12 days, depending on the species, in tropical areas. Once adulthood is reached, the aquatic phase is finished, and the adult female mosquito is then, ready to serve as host to the malaria parasite.⁷

The transmission of malaria is highly sensitive to climatic variation. Rainfall is important due to its effects on the mosquito life-cycle. First, rainfall provides "breeding sites" for the female *anopheles* mosquitoes to lay their eggs. The continuation of the rainfall may contribute to the development of the larvae and pupae into adulthood. Temperature also plays an important role in this process (Martens et al. 1995). The aquatic development stages of the mosquito occurs more efficiently in temperatures between $16^{\circ}C$ to $28^{\circ}C$ (Cervellati et al. 2018). Moreover, survival of adult mosquitoes also depends on temperature and rainfall, as well as humidity. Warmer temperatures decreases the incubation period ("extrinsic" cycle) of the parasite inside the infected female *Anopheles*, increasing the chances of transmission.

5. In Brazil, there are more than 50 species, including the *Anopheles darlingi* and *Anopheles gambiae*, which have biting preferences at the outdoors, making them highly effective vectors in the malaria transmission.

6. Common symptoms include vomits, diarrhea, acute fever, shivering, anemia.

7. On average, an adult *Anopheles* female mosquito can live for approximately 1-2 weeks.

Temperatures below 15°C for *Plasmodium vivax* and 20°C for *Plasmodium falciparum* break the extrinsic cycle, hindering the transmission.⁸

Taken together, this complex relationship between temperature and rainfall with the transmission cycle of malaria implies that outbreaks of malaria transmission are associated with a particular combination of the wet season and sufficiently high temperatures during the year; i.e., malaria transmission is characterized by a clear-cut seasonal component. I make use of this important mechanism in the transmission to identify the exposure during the first periods of life.

B Malaria history in Brazil

Malaria is believed to have been introduced in Brazil during the colonial times around 1560 and its spread throughout the country was triggered by the precarious conditions of infrastructure constructions (mainly railroads connecting various parts of the country) and the influx of the population to the Amazon region, where the geographic and climatic conditions for the survival of the *anopheles* mosquito are ideal, with the boom of the rubber industry (Griffing, Tauil, Udhayakumar, and Silva-Flannery 2015).

Early efforts to combat malaria were usually done at a case-by-case basis, with special attention to large public works projects.⁹ The common measures were mainly palliative, including the intake of chloroquine, an anti-malarial drug; the application of insecticides on water deposits near domiciles; drainage of water banks; distribution of bed nets, and destruction of mosquitoes breeding sites. The increasingly health hazard caused by malaria on public infrastructure projects and among the poor population, mainly in North and

8. The Extrinsic incubation period ranges from 10 to 21 days, whereas the intrinsic incubation period ranges from 7 to 30 days, on average, depending on the parasite species. For the *P. vivax*, the range is 12 to 17 days, whereas for the *P. falciparum* and the *P. malariae*, the ranges are from 9 to 14 and 18 to 40 days, respectively (Brasil et al. 2011). See <https://www.cdc.gov/malaria/about/biology/index.html>, accessed 08/30/2018, for detailed information about the biologic aspects of malaria.

9. During the early 1900s, Brazilian government aimed at expanding infrastructure in many remote areas and crews working on these projects fell victim to the disease, causing several construction sites to be interrupted or abandoned. Around that period, malaria was widespread in Brazil, with approximately 60 million cases – representing roughly 50 percent of the Brazilian population - being reported each year (Coura, Suárez-Mutis, and Ladeia-Andrade 2006).

Northeast regions, compelled some of the most prominent malarial experts in Brazil to urge for a centralized effort by the federal government to halt transmission of the disease, which started in 1941 with the creation of the National Malaria Service, the SNM (Griffing et al. 2015).

The insecticide Dichlorodiphenyltrichloroethane, commonly known as DDT, was first used in the anti-malarial campaign in an organized way in 1945; its success led to its widespread use in most of the states in the North region. By 1954, DDT spraying covered areas occupied by around 3 million people in all states, except São Paulo, which was incorporated into the campaign in 1959. In 1957, the SNM was renamed the Malaria Eradication Campaign (CEM), in response to the Malaria Eradication Program that the World Health Organization (WHO) had established in 1955. Figure 1 displays the distribution of malaria cases across states in Brazil in 1959, the first year in which the Ministry of Health began providing state-level malaria burden reports). As the figure shows, the Legal Amazon is the area with the highest incidence; some degree of heterogeneity surfaces in the remaining states.

The CEM was successful in eliminating malaria in four out of the five Brazilian regions, with the exception of the North. The failure of the CEM in the North region was primarily given by the resistance of the *P. falciparum* to chloroquine, lack of health and social infrastructure and a large number of people susceptible to the disease who were engaged in agricultural, mining, and rubber industries. The CEM was suspended in 1970 due to criticisms with respect to the administrative organization of the campaign and also given the relatively low and concentrated number of infections.

III Data and Empirical Strategy

The micro-level data for the individual-level analysis come from the annual Brazilian National Household Sample Survey (PNAD). I use the waves from 1992 to 2015 to construct

a sample of individuals aged 23 to 65; the sample includes birth cohorts from 1926 to 1999.¹⁰ Importantly, individuals are identified in the sample by location of birth rather than current residence. This formulation allows for a clearer interpretation of the findings, since results identifying individuals by location of residence would be contaminated by selective migration issues.¹¹ Additionally, information on month and year of birth for the sampled individuals allows me to link individuals' outcomes to specific conditions at the time and location of birth.¹²

I combine the micro-level data from various PNAD samples with state-level malaria transmission rates to build the data set used in this paper. To construct the malaria transmission risk, I use the monthly average number of reported cases of malaria at the state level from 2007 to 2017.¹³ The units of observation are expressed in terms of individual, month of exposure, year of birth, and state of birth cells. The month of exposure captures the risk of malaria transmission across months of the year, whereas year of birth links individuals to the prevailing scale of transmission. Figure 2 shows the average risk of malaria transmission across states in Brazil. The figure highlights the degree of heterogeneity in transmission in both state and month dimensions. Given the enormous geographic size of Brazil, climatic conditions and, thus, malaria transmissions, may vary substantially by state and seasons of the year.¹⁴

In addition to the monthly variation in malaria risk by state, I use the exogenous decline in

10. I exclude individuals born in the Amazon region because the eradication campaign was not successful in achieving the same dramatic decline in malaria rates as in the rest of the country due to the region-specific environmental and demographic conditions that favor the stability and proliferation of both malaria vector and parasite. The lack of variation of exposure across different cohorts during the eradication period would not allow for a clear comparison of cohorts born pre- and post-eradication.

11. It is possible that the most privileged (high-skilled) individuals migrate to areas in which the malaria burden is low. This selection channel is, thus, shut down in my analysis, in contrast with other studies identifying exposure according to location of residence due to lack of precise location of birth data.

12. Since the data on date of birth and age is self-reported, age heaping might affect my estimates if misreporting is systematically associated with individual socioeconomic characteristics. In appendix B1, I show that age heaping is not an important factor driving my results by analyzing the age distribution in my data according to socioeconomic status.

13. The data are provided by the Brazilian Ministry of Health – DATASUS. See Appendix A for a detailed description of the data.

14. Spikes in the reported number of cases frequently happen during wet seasons, which vary by regions in Brazil.

the overall scale of transmission after the eradication efforts started in 1957. The magnitude of the reduction is shown in figure 3. The first observation, from Griffing et al. (2015), corresponds to estimates of malaria country-wide malaria cases prior to the campaign era. The remaining data points are from Ministry of Health, which records data on the number of cases reported annually, starting from 1959.

Research Design

Taken together, figures 2 and 3 show the relevant variation of malaria transmission to identifying in utero exposure to malaria. The first aspect of malaria transmission that this paper explores is its seasonal variation related to specific climatic conditions, as figure 2 displays. I make use of the differential timing of exposure to malaria during early periods of life to assess the long-term effects on adult human capital and socio-economic outcomes. The second feature of the research design makes use of the exogenous sharp decline in malaria transmission after the enactment of the Malaria Eradication Campaign in 1957, highlighted in figure 3, to assess the effects of differences in exposure of cohorts born shortly before and immediately after the reduction.¹⁵

The baseline specification identifies exposure to malaria as the average risk of transmission across the months, year, and state in which the individuals were exposed while in utero. For example, consider a given individual, born in month m , year y , and state s ; her exposure is given by the average risk associated with months $m - 9$ through $m - 1$ in state s and year y .¹⁶

I construct the main independent variable in the analysis by combining the 2007–2017

15. A potential concern is that the eradication efforts might also have reduced the incidence of other vector-borne diseases such as yellow fever and dengue. Therefore, it is possible that my estimates are picking up the effects of other vector-borne diseases besides malaria. Appendix B.3 discusses the estimates for the prevalence of such diseases during the period analyzed in this paper and concludes that, although present in Brazil, the number of cases of both yellow fever and dengue was in a much smaller scale compared to malaria incidence and are likely to contaminate the estimates below.

16. If parents are able to systematically choose the month of birth of their offspring in response to seasonal malaria burden, my empirical strategy would likely be biased towards my estimates. In appendix B.7, I find no statistical association between individuals' month of birth and underlying socioeconomic characteristics which would suggest that timing of birth is endogenous.

state-month-level reported malaria cases data with state-level data available from 1959 onward, based on some assumptions about the dynamics of the state-month level malaria transmission through time.¹⁷ Formally, the exposure variable can be decomposed in two main components: the overall nation-wide scale of transmission and the relative intensity at the month-state level, in the following way:

$$\text{Exposure}_{sky} \approx \text{SCALE}_y \times \text{REL}_{sk}, \quad (1)$$

where Exposure_{sky} , the average exposure in month k of year y for each state s , is defined by the decomposition of the overall scale effect, SCALE_y , measured as overall total number of cases in year y , and the relative intensity of malaria transmission across months and states, REL_{sk} , which is captured by the average number of reported cases between 2007 and 2017 at month k and state s as a ratio of the state-level mean number of cases throughout the given period.¹⁸

The implicit assumption carried out throughout the analysis, then, is that relative risk across month-state cells is constant across time. The implication of this assumption is that the eradication efforts was homogeneous across the country and did not affect the relative intensity of the monthly variation in malaria transmission. Its only effect was through the decline in the scale of overall transmission.¹⁹ The constructed measure to represent in utero exposure of individuals born in month m , state s , and year y is given by

17. Ideally, the measure of risk of malaria transmission would rely on average monthly malaria cases during the period around the eradication era. However, due to data limitations, monthly malaria cases can only be observed for the period 2007–2017, as detailed above.

18. Specifically, I construct Exposure_{sky} as the ratio of average monthly-level number of reported cases to the mean number of cases between 2007 and 2017, at the state level, multiplied by the ratio of the state-level total number of cases in year y , per 1,000 inhabitants. For the years before 1959, for which overall malaria burden is unavailable, I consider the observed incidence in the year 1953, from Griffing et al. (2015).

19. The analysis essentially assumes that if the observed likelihood of being infected with malaria in state s at month m is twice as much as the one observed in state s' and month m' in 2007, it is also twice as likely to be infected with malaria in state s at month m relative to state s' and month m' in the years around the eradication era. Appendix C discusses the validity of this assumption in a great deal of details, including potential biases in the estimated results if the underlying assumption fails to hold.

$$Exposure_{sm_y} = \sum_{k=m-9}^{m-1} REL_{sk} \times SCALE_y,$$

where REL_{sk} denotes the average risk of transmission in month k and state s , as described above.

I consider individuals born shortly before and shortly after the sharp decline in malaria transmission to estimate the effects of early life exposure to malaria on socioeconomic conditions. The baseline equation to be estimated is given by

$$Outcome_{ism_y} = \beta Exposure_{sm_y} + \alpha_c + \gamma_s + X'_{ism_y} \phi + \varepsilon_{ism_y}, \quad (2)$$

where $Exposure_{sm_y}$ is defined as the risk of transmission at a given month of birth m and state of birth s . I estimate equation 2 for two consecutive birth cohorts: 1959 (pre-eradication) and 1960 (post-eradication). Individuals born in 1959, in general, were largely exposed to malaria transmission while in utero, while postnatal exposure was shortened.²⁰ Individuals born in 1960, on the other hand, were relatively less exposed throughout their early life period. Any effect of malaria exposure during pregnancy should be seen in the estimation of equation 2 for the pre-eradication birth cohort, while the treatment effect of early life exposure on individuals members of the post-eradication birth cohort – the placebo birth cohort group – is expected to be very small (if any). The large estimated decline in the malaria burden between these two adjacent years is of extreme relevance to compare outcomes of cohorts whose in utero exposure to malaria was dramatically different.²¹ The identifying assumption of the research design, thus, is that any unobservable factors that affect human capital accumulation vary continuously over time (at least during the time

20. According to the WHO, DDT spraying total coverage started in August, 1959.

21. The rate of transmission plummeted from an estimated 97 cases per 1,000 inhabitants per year, in 1953, to only 0.63 cases per 1,000 inhabitants per year in 1960. Assuming a linear path in the yearly reduction along this period, malaria rates would have been around 14.40 cases per 1,000 inhabitants per year in 1959; this corresponds to 22.85 times the intensity of exposure in the following year. However, considering the time of personnel training, and bureaucratic delays in the initial stage of the eradication, the decline in the malaria burden from 1959 to 1960 is likely to be larger.

frame considered in this paper).

An important concern is that individuals born at the beginning of 1959 were more exposed than individuals born at the end of that year. By the same token, individuals born in the initial months of 1960 are likely to have had some exposure while in utero. I abstract from the complication of partial exposure and consider all individuals members of the 1959 birth cohort to be fully exposed while in utero, while all members of birth cohort 1960 are considered not exposed. I make this simplifying assumption for two main reasons. First, due data limitations, I cannot establish the exact reduction on malaria rates prior to the eradication era at a monthly level. Second, the results are robust to restricting the date of birth to specific month brackets around the years of 1959 and 1960.²² Additionally, in appendix B.6, I construct broader definitions of birth cohorts for the analysis to ensure that pre-eradication birth cohorts were indeed exposed. The results are qualitatively similar across different birth cohorts.

According to epidemiological studies, infections in different timing of fetal development might lead to different paths of effects on cognition and health development (Smith 2004; Menendez 1995; Matteelli, Caligaris, Castelli, and Carosi 1997; Umbers, Aitken, and Rogerson 2011). In light of this potential heterogeneous treatment effects during different periods of early life, I employ the same strategy as defined above to identify early life exposure at the trimester level. In particular, I construct an exposure variable for each of the three trimesters of pregnancy as the average risk of transmission during the corresponding three months of exposure as

$$Exposure_{ms}^T = \sum_{i=m-k}^{m-n} REL_{si} \times SCALE_y,$$

where $k = 9, 6, 3$ and $n = 7, 4, 1$ whenever $T = 1, 2, 3$, respectively. The trimester exposure analysis, then, can be represented by

22. However, for some specifications in which I impose strong sample size restrictions, the results become imprecisely estimated, despite the large effects suggested by the estimated coefficients.

$$Outcome_{ismy} = \beta_1 Exposure_{msy}^1 + \beta_2 Exposure_{msy}^2 + \beta_3 Exposure_{msy}^3 + \alpha_c + \gamma_s + X'_{ismy} \phi + \varepsilon_{ismy}, \quad (3)$$

where the variable definitions are as above.

The empirical strategy described above has some limitations and challenges that are worth mentioning. First, general equilibrium effects might be at play; for instance, assuming that decline in malaria rates lead to higher human capital, the rate of return to these investments would increase among more exposed individuals. These effects might also spill over to non-exposed groups. The net general equilibrium effect in this situation is uncertain. Second, malaria infections might cause the death of the weakest individuals, causing a selection problem in the analysis, with the parameters being estimated with an upward bias. In appendix B.1, I show that mortality selection is not a first-order issue in my main analysis. Another important concern is that the constructed measure of malaria exposure is contaminated with measurement error. Appendices B.4 and B.5 provide Instrumental Variables estimates corroborating the main findings of this paper.

IV Results and Discussion

To estimate the effects of in utero malaria exposure on adult outcomes across treatment and control groups (1959 and 1960 birth cohorts respectively), it is necessary that individuals are similar along different socioeconomic dimensions to ensure comparability across both groups. Table 1 describes the summary statistics for the main variables analyzed in this paper for the 1959 and 1960 birth cohorts separately. In general, both samples are similar in all dimensions, suggesting balance across individuals on different group cohorts, on average.

The first set of results below addresses estimates of in utero exposure as the average risk of malaria transmission throughout the pregnancy period. Next, I address timing of exposure in different trimesters of the pregnancy to account for heterogeneous effects of exposure in

different critical periods of gestation. Then, I consider the potential long-term consequences of in utero exposure to malaria on a range of different socioeconomic conditions as well as potential differential treatment effects across the income distribution.

A Average In Utero Effects

If early life exposure to malaria affects long-term outcomes, the baseline estimation in equation 2 should display stronger effects on the pre-eradication period. Since the sample is restricted to only two consecutive birth cohorts, any differences in long-term outcomes can plausibly be attributed to the effects of changes in the early-life environment. Panel A of table 2 shows the estimation results for the 1959 birth cohort sample.²³ The results suggest a statistically significant effect of early life exposure to malaria on educational attainment for the pre-eradication birth cohort sample. Individuals in utero in months with higher risk of exposure to malaria, on average, have less years of education than less-exposed individuals during the same period, as shown in column (1). Column (2) performs the previous estimation including state-of-birth fixed effects, which essentially captures the effect of monthly-level differences in malaria exposure by shutting down the between-states variation mechanism. The size of the coefficient is somewhat smaller but still economically meaningful and statistically significant, corroborating the hypothesis that within-state seasonal exposure to malaria is an important component of the main overall effect.

In order to directly interpret the coefficients of the above results, and to assess the magnitude of the effects, one might need to adjust for the scale of the transmission in different periods.²⁴ The results in table 2 indicate a negative effect of in utero exposure to malaria on years of education and primary completion on exposed cohorts (born in 1959). The point estimate for the effect of in utero exposure on educational attainment is -17.52

23. All coefficients are from regressions using the full set of controls, which include gender, age, race, sector of activity, migration and rural status. Moreover, standard errors are clustered at the state-month level.

24. Although the independent variable of the analysis is expressed in terms of number of cases, it does not carry a direct interpretation of the magnitude of the estimated coefficients, since I construct a *relative* measure of malaria intensity based on available incidence data.

(column 2). The mean value of the in utero risk is 0.0436, with a standard deviation of 0.0029. An increase in malaria risk in the magnitude of one standard deviation would induce an effect of 0.0029 times the estimated coefficient. Therefore, a one standard deviation increase in exposure, as measured by the risk of in utero malaria infection, leads to, on average, 0.0516 fewer years of education. Carrying out the same computations above for the primary degree coefficient (-1.634), a one standard deviation increase of malaria risk would generate an estimated reduction of 0.48 percentage points the probability of completing primary education. The results in Panel A further indicate statistically significant treatment effect of in utero exposure to malaria on secondary education completion, although smaller in magnitude and less significant. The small effect size on higher education seems to suggest that early life malaria exposure affects different socioeconomic groups of the population in an heterogeneous manner, given that black (including *pardos*) and poor population in Brazil are disproportionately less represented in college enrollment rates.²⁵ Finally, Panel B provides the same estimation carried out in Panel A for the 1960 birth cohort. Individuals born in the subsequent year, when malaria rates have largely declined, do not show any statistically significant differences in any of the analyzed outcomes according to their early life exposure, as expected.

B Exploring Heterogeneous Effects According to Different Trimesters of In Utero Early Life

In this section, I consider exposure in all three trimesters of pregnancy to check for heterogeneous effects of timing of exposure. Table 3 shows the estimation of equation 2 for exposure in each trimester of pregnancy for both birth cohort groups (1959 and 1960).

The results indicate a negative and statistically significant long-run effect of exposure dur-

25. For example, in my sample, 13.6 percent of whites have completed tertiary education, whereas this share is only 5.3 percent for non-whites. College degree is also unequal across the income distribution: among the bottom 10%, only 2.5% of the individuals in the sample have college degree, whereas this share is about 16.9% among the top 10%. I return to the issue of the heterogeneity of the results in section IV.C.

ing the first three months of pregnancy on human capital accumulation in the pre-eradication birth cohort, as observed in Panel A. In general, higher in utero exposure to malaria during first trimester leads to less years of education and lower likelihood of primary as well as secondary completion. The point estimates are qualitatively similar to ones detailed in table 2, albeit somewhat larger magnitudes. In fact, these results seem to corroborate theoretical predictions in which fetal growth restrictions caused by malaria infections might have more severe consequences during the first trimester of pregnancy, when the impairment of fetal development is made in a symmetric manner. Fetuses with symmetric growth restrictions are more likely to develop permanent neurological sequelae (Umbers, Aitken, and Rogerson 2011).

Exposure to malaria in the second trimester of pregnancy seems to also have negative impact on years of education, albeit a smaller treatment effect when compared to exposure during the first trimester.²⁶ The results also do not indicate any treatment effect of exposure during the second trimester on the other outcomes, as shown in columns (3) through (8) of table 3. Additionally, third trimester malaria exposure does not seem to be associated with long-term consequences for any of the analyzed outcomes. The results for the post eradication sample in Panel B indicate no exposure effects on educational outcomes, except for secondary education, during the first trimester, as shown in column (5) of table 3.

C Discussion and Extension of the Main Results

Other Socioeconomic Outcomes

Given the sizable negative effects of in utero exposure to malaria on educational attainment, I test whether these effects are also observed in other socioeconomic outcomes. Particularly, in table 4, I provide the estimates for both average (Panel A) and trimester

26. However, the results are only statistically significant at the 10% level for the specification with state-of-birth fixed effects. These results are in line with Desai et al. (2007) and Singh, Shukla, and Sharma (1999), who conclude that malaria infections during the second trimester may lead to greater likelihood of low birth weights and pre-mature births.

effects (Panel B) of in utero exposure to malaria on literacy, personal income, and whether the individual works in the agricultural sector for the two consecutive birth cohorts (1959 and 1960). First, there does not seem to be any significant effects of timing of in utero exposure on either literacy or personal income on either cohort (columns 1 through 4).²⁷ Another important socioeconomic outcome that might have been affected by early life health shocks is the sector of activity in which individuals work.²⁸ Columns (5) and (6) address the question of whether early life exposure to malaria during the Eradication era might have played a role in this process. As the results show, the point estimates for both birth cohorts are positive, suggesting that early life exposure to malaria is associated with a higher probability of working in the low productivity agriculture sector, although only statistically significant and larger in magnitude for the pre-eradication group, as expected.

Heterogeneity of the Effects

Across the Income Distribution: Given the main effects of in utero exposure on educational attainment reported in tables 2 and 3, a natural subsequent question is whether these results are observed across all the income distribution. To answer this question, I re-estimate the model for different quartiles of the income distribution, as shown in table 5.

In general, in utero malaria exposure reduces years of education on first and third quartiles. Primary education completion is affected by in utero exposure only for the individuals at or below the second quartile, whereas the effects on secondary and tertiary degrees are observed on the third and fourth quartiles of the income distribution, respectively. These results are intuitive since lower income population groups generally do not have access to

27. On a theoretical note, Bleakley (2010a) points out that the economic decisions about human capital investments depend on both the discounted benefits of one additional year in school (higher adult productivity) and costs (either in the form of implicit opportunity costs or forgone wages in the labor market). Lower levels of initial physical health endowments or cognitive abilities might lead to both a decline in productivity due to lower health, and to a decline in opportunity cost of schooling, due, perhaps, to a decline in the potential forgone wages. The net effect is ambiguous, in theory. Thus, the effect of the health shock on education and income might not be associated.

28. Sector of activity might provide additional (and a less noisy) information about the socioeconomic status of the individuals in the sample.

higher degree education, and only exposed individuals at the top of the income distribution are less likely to complete either secondary or tertiary education. Importantly, the observed treatment effect of early life exposure to malaria on primary completion only on lower-income groups can shed light on the potential exacerbation of inequality by the differential impacts from exposure to early life insults.

Across Socioeconomic Groups: Another important dimension of heterogeneity of the effects is related to the socioeconomic and demographic characteristics of the population. In this section, I estimate the long-run effects of in utero exposure to malaria across race and gender, documented in table 6. Rawlings (2016), for example, found consistent heterogeneity of the effects of early life exposure to a malaria epidemic outbreak in two states in Brazil across gender and race, with the results suggesting important selection effects, specifically among the non-white women group.²⁹

While higher in utero exposure to malaria for whites is associated with lower probability of completing both primary and secondary degrees, the effects are somewhat smaller and not significant among non-whites on the 1959 birth cohort. Selection effects are a possible factor mitigating the *scarring* negative effects observed on non-white individuals, usually the demographic group facing the most challenging early life circumstances (Marteleto 2012; Wood, Carvalho, and Horta 2010; Barros, Victora, and Horta 2001; Gradín 2009).³⁰ The results in table 6 further indicate net *scarring* effects of in utero exposure to malaria on both men and women. In general, the effects are somewhat stronger for primary completion on women, again suggesting that a selection mechanism might be at play given that male fetuses are usually more vulnerable to environmental shocks than female ones. It is worth noting further that I find little to no effect of in utero exposure to malaria for the 1960 birth cohort, further corroborating the hypothesis that this particular comparison group has

29. There are two competing effects that might determine the long-run consequences of in utero exposure to environmental factors, such as malaria incidence: a (negative) *scarring* effect on the survivors' educational attainment, and a (positive) selection effect, which happens when only the healthiest individuals survive.

30. In Brazil, race can be used as a *proxy* for socioeconomic status (SES), given the sizable correlation between them (Rawlings 2016; Harris et al. 1993; Barros, Victora, and Horta 2001).

indeed received a placebo treatment.

Despite the evidence for potential selection effects discussed above, it is important to note that it is likely to play a limited role in my estimates, as opposed to Rawlings (2016)'s, in which selection dominates the net effect on the estimates for men, for example. Indeed, Kudamatsu, Persson, and Strömberg (2012) finds that selection might be a more important contributing factor to the overall effects in epidemic locations relative to endemic ones (Rawlings 2016).

V Conclusions

Differences in initial health stocks across individuals and locations are associated with lifetime socioeconomic conditions. Causal interpretation of this connection requires a carefully designed research strategy, since unobserved socioeconomic differences across different groups of people might otherwise overstate the relative importance of early life health. From a theoretical perspective, initial health might affect the path of health capital, which determine different dimensions of one's capabilities, such as educational attainment, labor productivity, and fertility. Establishing and quantifying this relationship might help policymakers in the elaboration of developmental policies to improve living standards in areas in which adverse health environment, such as the presence of infectious diseases, exposure to pollution, or a lack of basic sanitation, might disproportionately affect highly exposed pregnant women during their early life.

This paper explores two sources of variations in malaria risk in Brazil as proxies for exogenous shocks on initial health, which affect otherwise similar individuals in heterogeneous ways. The first source of variation relies on the month of birth to identify degrees of exposure according to seasonal variations in malaria transmission risk. Individuals who are potentially at greatest risk of experiencing long-term effects are those whose gestation periods encompassed a longer period with climatic conditions favoring mosquito and vector proliferation;

by contrast, individuals in the same locations but whose gestation period encompassed a shorter period of such conditions face comparatively lower risks of long-term effects. The second source of variation is based on the large and rapid overall decline in malaria burden in Brazil after governmental eradication efforts to identify the extent of the in utero exposure.

The results found on this paper suggest that initial health plays an important role in adult human capital accumulation. In practical terms, accounting for other factors, such as demographic characteristics and state-level attributes, a given individual born in either January or December in the state of Paraíba, in the Northeast region (fifth percentile of the malaria risk distribution), would attain roughly about half 0.2 years more of education, and be 2 percentage points more likely to be primary graduate than an individual born in April in the State of Goiás, Mid-West (ninety-fifth percentile of the malaria risk distribution).

An additional feature of the findings is that first trimester of pregnancy seems to be the most critical period; malaria infections that occur in these period have the largest effects. One possible theoretical explanation for this result is that fetal growth restrictions during the very beginning of life affect nervous system development in a very strong and permanent manner. Moreover, the poor population face stronger effects, given the lack of sufficient and adequate resources to protect against malaria exposure or even treatment upon infections. Therefore, policies devoted to improve socioeconomic conditions in afflicted areas would likely be effective and achieve long-run desired outcomes should they target low-income and pregnant women, the vulnerable socioeconomic groups – especially those in early stages of gestation. The results in this paper suggest potential future relative gains in socioeconomic conditions for these particular groups.

Further research in this area might help shed light on the specific mechanisms that lead to the results obtained by this paper. For example, one might estimate the in utero effects of exposure to malaria transmission on general and specific health, such as likelihood of developing different morbidities in adulthood, as well as its impact on life expectancy and adult mortality. Moreover, since the effects of malaria on educational attainment are thought

to be the result of impaired cognitive development, one could potentially observe effects of exposure on cognition test scores across school-aged children. Unfortunately, comprehensive official micro-level data on test scores are only available starting from 1995, after the malaria eradication efforts. Finally, testing the specific relationship of this paper in different contexts, with different data sets and a range of different outcome variables might help testing the external validity of this study.

Appendix A. Data sources and Details

Malaria Variables

Malaria Risk

The malaria risk variable is constructed using malaria reported cases at the month-state level for the period between 2007–2017. In order to construct the variable at a per capita basis, I collect state population data from IPEADATA³¹. The malaria risk variable is number of reported cases per 1,000 inhabitants for a given state and month.³²

Malaria Index

The mortality selection estimation makes use of a state-level time-invariant measure of malaria transmission, which is constructed by using the ecology-based spatial Malaria Stability Index (MSI) proposed by Kiszewski et al. (2004). The index captures geographical distribution of the dominant *Anopheles* mosquito as well as information on climatic and geographic conditions that contribute to the survival and spread of vector and parasite. Using a Geographic Information System (GIS) software, I overlay a Brazilian map with state boundaries over the global spatial Malaria Index map and generate state-level averages of the index. The resulting index is defined as

$$\sum_{m=1}^{12} a_{i,m}^2 p_{i,m}^E / -\ln(p_{i,m}),$$

where m = month, i = identity of the dominant vector, a = proportion of biting people (0-1), and p = daily survival rate, and E = Extrinsic incubation period in days. Figure A1 below depicts the distribution of the

31. <http://www.ipeadata.gov.br/Default.aspx> Accessed on 10/17/2018.

32. Population data is given at an yearly basis. I use the same constant population for each month in a given year.

MSI in Brazil.

Individual-level outcomes and controls

Education

The education variables used throughout the analysis are number of years of education which corresponds to the number of completed years in school, as well as indicator variables for degree completion, which are constructed based on the survey question referring to the last completed degree. The primary source is the Brazilian National Household Sample Survey (PNAD).

Income

Income is given by the hourly earned income from main activity in the previous week. In the survey, income is reported at a monthly basis. I transform monthly income to hourly income by multiplying reported hours worked weekly by 52 (total number of weeks in a year) and divide by 12 (total number of months). I drop from the analysis observations whose hourly income is higher than 90 percentile. In the analysis, I use the natural log of income. The primary data source is the Brazilian National Household Sample Survey (PNAD).

Health

The health variable is given by the self-reported general health status. Respondents categorize their perceived general health by reporting a number from 1 (excellent) to 5 (poor). The primary data source is the Brazilian National Household Sample Survey (PNAD).

Demographic control variables

Gender: dummy variable indicating whether the individual is a female.

Race: dummy variable indicating the self-reported individuals' race.

Mover: dummy variable indicating whether the individual resides in the state of birth.

Age: constructed variable, based on self-reported individuals' date of birth.

Sector of activity: Sector of main activity in the previous week. I define the following groups as separate sectors of activity: agriculture, manufacturing, construction, other industries, services, transport and communications, public administration, and other activities.

The primary data source is the Brazilian National Household Sample Survey (PNAD).

Climatic Variables

In the Instrumental Variables estimation, I use average monthly temperature and precipitation as excluded instruments for the malaria transmission variable. The data source is WorldClim – Global Climate Data (v.2), available at <http://worldclim.org/version2>. The climatic data set is based on a raster file with 10 km^2 resolution cells, with mean monthly temperature and precipitation for the period 1970–2000. I construct state-level monthly averages by overlaying a Brazilian georeferenced map with state boundaries with the help of a GIS software.

Appendix B. Sensitivity Analysis

In this section, I discuss several possible alternative mechanisms that might affect the main results of this paper. First, I address the issue of mortality selection by analyzing the exposure effects on the likelihood of stillbirths for childbearing-age women during the period in which the disease was endemic. Second, I discuss the potential issue of age heaping in my data, followed by the role of other vector-borne diseases in explaining the results in my analysis. The subsequent section deals with potential omitted variable bias and measurement error in my main specification. Specifically, I construct a set of instruments based on the intrinsic relationship between malaria transmission and climatic factors, namely temperature and precipitation. The plausibility of the exclusion restriction assumption of the Instrumental Variables estimation is discussed in the following subsection. Next, it is possible that the observed effects are not robust to different choices of cohorts (both high versus low in utero exposure). I address this issue by testing different timings of birth in defining exposure across cohorts. Finally, I address the potential endogeneity associated with timing of birth.

B.1 Mortality Selection

If the most vulnerable and weakest individuals do not survive in utero exposure to malaria, the previous results are potentially biased due to selection on mortality. Early life exposure to health shocks affect both the unobserved distribution of initial health endowments and the health threshold level at which survival to infancy occurs. Whenever mortality increases due to negative health shocks (such as early life exposure to malaria), the initial health distribution shifts, which implies lower lifetime health. However, when the health shocks lead to greater fetal mortality, then the implication for general subsequent health is the opposite: the fetuses that survive to infancy will likely be healthier than if the in utero health shock had not caused greater mortality rates. If the latter effect prevails, the

results would be biased against my estimation results.

The concern that mortality selection is a potential source of bias on my results are alleviated by the fact that the most prevalent parasite in Brazil, the *P. vivax*, rarely causes death, compared to the *P. falciparum*, which is commonly found in Sub-Saharan Africa.³³ I address the issue more formally by testing whether more exposed women at childbearing age during pre-eradication era (i.e. born prior to 1914) had higher likelihood of miscarriages or stillbirths.³⁴ In particular, I use number of deceased children while in utero as the dependent variable, and I use a state-level malaria ecology-based index (henceforth MSI) , which captures the stability and strength of malaria transmission, as the main independent variable. The estimation uses the following set of controls: race, migration status, whether the respondent lives in a rural area, sector of employment, age, year of birth, and number of children.³⁵ All estimates also include birth cohort fixed effects, state of birth fixed effects.

The results are shown in table B1. Column 1 tests whether differential exposure to malaria prior to the eradication era is associated with differences in the number of miscarriages and/or stillbirths.³⁶ Columns 2 and 3 break down the analysis for boys and girls, whereas column 4 displays the results of a Linear Probability Model (LPM) where the dependent variable is an indicator of whether the respondent has ever had either a miscarriage or stillbirth. The results indicate no relationship between malaria burden and mortality differences among women who experienced greater or lesser levels of exposure to the disease.

An important limitation of the above analysis is that miscarriages are likely to be considerably underreported, since most of them happen within the first weeks of gestation, when the mothers might not even be aware of the pregnancy. Column 5 addresses this issue by reporting the effects of exposure to malaria on the sex ratio of births among childbearing

33. *P. falciparum* is also common in the Amazon region in Brazil. However, this is not a concern since I drop Legal Amazon states from the analysis.

34. Introducing younger cohorts only corroborate the main results of this section.

35. It is important to control for the number of children, since, according to Regan, Braude, and Trembath (1989), prior live births affect the likelihood of miscarriages.

36. Stillbirth is defined as an infant death after survival of the first 28 weeks of in utero life. Death prior to this date is considered miscarriage.

aged women prior and post eradication. Specifically, I run a Differences-in-Differences (DID) model, where the (continuous) treatment variable is the malaria stability index interacted with the *Post* dummy, indicating whether the individual has spent her childbearing period after the eradication period, as defined below:

$$Sex\ ratio_{ismy} = \beta MSI_s \times Post + \gamma Post + \eta MSI_s + \alpha_c + X'_{isy} \times Post\phi + \varepsilon_{isy}, \quad (4)$$

where $Sex\ ratio_{isy}$ is defined as the number of surviving boys relative to the number of surviving girls for each woman i aged 45 or more, born in state s and year y ; $Post$ is a dummy variable indicating whether the individual was born after 1960; α_c is a cohort-specific fixed effects term; X_{isy} is the vector of sociodemographic controls used on the previous estimations, including a term capturing state-specific time trends to partially control for inherent differential pre-intervention trends across different states.

If mortality selection is an issue, the data should display a relatively larger imbalance towards a higher sex ratio (boys relative to girls) for individuals born post-eradication era. This expected result is based on the widely observed fact that female infants are more likely to survive to negative shocks during in utero life (Waldron 1983; Astolfi and Zonta 1999; Kraemer 2000; Zaren, Lindmark, and Bakketeig 2000; Sakamoto, Nakano, and Akagi 2001; Barker 2004; Catalano, Bruckner, Anderson, and Gould 2005; Catalano, Bruckner, Marks, and Eskenazi 2006). The results in column 5 show no significant change in the sex composition of births after the eradication relative to births prior to the eradication period, although the sign of the estimated coefficient suggests a relative increase in the sex ratio in favor of male children being born after the improvement in the early life health environment.

Besides the fact that the prevailing malaria parasite in Brazil is mildly lethal, the evidence collected in this section does not seem to indicate that the main results of this paper are driven by selection due to mortality of the weakest fetuses.

B.2 Age Heaping

In self-reported survey data, such as the PNAD, individuals might misreport their age, approximating it to the nearest round number. This might result in a potential source bias if the misreporting is systematically correlated with individual characteristics, such as socioeconomic status. To detect such anomaly in the data, figure B1 reports the distribution of the reported age structure of the sample by different quartiles of the income distribution. As observed, age heaping does not seem to be an important issue driving the results above. Nevertheless, I re-estimate the models above, excluding individuals with ages ending in either 0 or 5. The results do not contradict the previous findings.³⁷

B.3 Other Vector-Borne Diseases

A possible confounding factor that might inflate the estimates of the long-term effects of early-life exposure to malaria is the role played by the eradication campaign in reducing the transmission of other vector-borne diseases such as yellow fever and dengue. Both diseases are transmitted by the same vector, the *Aedes aegypti*, which was eradicated in Brazil by 1955.³⁸

Although the individuals in our sample might have been exposed to yellow fever and dengue during childhood, it is not likely that this effect is substantial enough to contaminate the main estimates. The national efforts in an eradication campaign of the *Aedes aegypti* had started more than ten years before the malaria eradication campaign, in 1942 (Catão 2011).³⁹ Moreover, during the time of its highest incidence rates, dengue was not an important public health problem. In fact, endemicity rates were lower in Brazil than in other countries of the American continent (Catão 2011).

37. Results are available upon request.

38. Brazil was officially recognized as having eradicated the *Aedes aegypti* in 1958. However, the mosquito was reintroduced in the country around late 1960s and early 1970s (Teixeira and Barreto 1996).

39. However, the vector was reintroduced in the Brazilian territories in the following decades for consecutive times (Catão 2011).

Additionally, Benchimol (1994) reports a relatively small number of cases of yellow fever between 1957 and 1959 (37 cases in three different states) in Brazil. Subsequent outbreak episodes in different regions has led to spikes in yellow fever cases, reaching 167 potential cases in the South in 1966. For comparison, the smallest number of malaria cases, after the success of the DDT spraying and antimalarial distribution was around 36,900 cases, in 1961 (Ferreira and Castro 2016).⁴⁰

B.4 Instrumental Variables Approach

One potential concern in the analysis is that the constructed exposure variable may suffer from measurement error or omitted variable bias, and thereby may not be able to fully account for truly exogenous variations in the risk of malaria transmission. One example of a possible bias is that higher-income states are more capable of diagnosing and reporting malaria than lower-income states, with poorer health institutions. Alternatively, malaria can be misreported when mistakenly diagnosed as a different disease.⁴¹ If this under-reporting is associated with regional characteristics, such as average educational levels, my results would suffer from attenuation bias. In my main specification, this concern is alleviated by the fact that I make use of within-state variations in exposure to malaria by leveraging on the seasonal differences in the reported cases due to the combination of high temperatures and rainfall.⁴² Nevertheless, I discuss the sensitivity of my results to such potential biases by instrumenting the risk of malaria transmission with specific climatic factors that affect the distribution and survival of both the mosquito and parasite of malaria.⁴³

I leverage on the biological and climatic aspects that determine the malaria vector survival and proliferation likelihood and identify short-term exposure to malaria as a function

40. Bleakley (2010b) reports similar figures for Colombia: 22 reported cases of yellow fever and 167 leishmaniasis cases during 1962. The number of malaria cases for the same year was 21,245.

41. The most common symptoms of malaria are similar to other diseases caused by viruses, such as the Flu.

42. I compare, therefore, individuals born in the same state and year, controlling for potential state-level unobserved factors, in different months.

43. If the measurement error is classical, the instrumental variables approach will produce consistent estimates.

of monthly climatic variations, which capture the intrinsic relationship between vector and parasite development with temperature and precipitation both across space and seasons of the year. Malaria transmission is highly sensitive to climatic variations within the year. Warm temperatures are needed for survival of both parasite and vector. Additionally, rainfall augments opportunities for the proliferation of the *Anopheles* mosquitoes by creating breeding sites where eggs can be deposited.⁴⁴ The first stage estimating equation can, thus, be described as

$$Exposure_{smy} = \alpha + Temp_{smy}\psi_1 + Prec_{smy}\psi_2 + \epsilon_{smy}, \quad (5)$$

where $Temp_{smy}$ and $Prec_{smy}$ represent quarterly average temperature and precipitation (and squared terms) faced by individuals born in state s , month m , and year y .⁴⁵ The second stage of the estimation is analogous to equation 2.

Table B2 describes the two-stage least squares (2SLS) results of the IV estimation. Column (1) shows the IV results for years of education of the 1959 birth cohort, whereas column (2) displays the result for the 1960 birth cohort sample. I also report the first stage F test statistics from all regressions, indicating a strong first stage of the 2SLS estimation.⁴⁶ The 2SLS estimation produces more precisely estimated treatment effects for average in utero exposure on years of education on the more exposed birth cohort. The estimated coefficient is larger in magnitude than the OLS estimates and statistically significant at usual confidence levels. The point estimate for the 1959 sample is six times greater in magnitude than for the the 1960 sample, which is not statistically significant. The remaining columns in table B2 show the IV estimates for the effects of in utero exposure to malaria on the likelihood of

44. See Section II.A for further discussion on the relationship between short-term malaria outbreaks and climatic variation.

45. Although I am not able to directly assess the validity of the exclusion restriction assumption, it is worthwhile noting that the first stage above captures the *joint* effect of the quarterly temperature, rainfall, and squared terms on exposure to malaria. The first stage of the IV estimate, thus, relies on the *simultaneous* importance of both variations. See section B.5 below for further discussion on the plausibility of the exclusion restriction in my analysis.

46. All statistics are greater than the commonly used value of 10 as a rule of thumb, suggested by Staiger and Stock (1997).

graduating primary through tertiary degrees. The 2SLS results find statistically significant average treatment effects, at a least 1% significance level, for primary completion from the 1959 birth cohort, whereas the results for the 1960 birth cohort, as expected, are smaller in magnitude and not statistically significant.

Table B3 reports the IV estimates according to the different trimester of in utero exposure to malaria. Compared to the OLS estimates, the IV results suggests larger treatment effects from in utero exposure during different gestational periods. Across all estimates for the 1959 cohort, the effects seem to be stronger during first and last trimesters (although the results are more precisely estimated for the first).

In general lines, the first three months of in utero life seems to be an important factor contributing to brain development and associated long-term negative consequences of fetal growth and cognition. A one standard deviation in the in utero exposure measure during the first trimester reduces education by 0.43 years (6% of the mean) and is associated with a reduction in the probability of primary completion of about 4.5 percentage points, as well as a decline in the likelihood of secondary and tertiary education by 2.78 and 0.89 percentage points, respectively. The 1960 birth cohort does not seem to exhibit statistically significant effects from in utero exposure to malaria over different trimesters of gestational life, as suggested by columns (2), (4), (6), and (8) in table B3.⁴⁷

Collectively, the results of this section further underscores the long-term effects of in utero exposure to malaria on human capital accumulation. The findings suggest that the timing of exposure is paramount, and that the critical period of exposure is very early, during the initial three months of fetal development. The strong effects observed on educational attainment might suggest that first-trimester infections, by delaying or hampering brain development, might affect cognition, leading to worse educational achievement.

47. Additionally, first stage F statistics are sufficiently high to meet the rule of thumb requirement for a strong first stage estimate, as suggested by the table.

B.5 Climatic Confounders

Since malaria transmission is intrinsically correlated with climatic and geographic factors, it is possible that the measure of malaria intensity is correlated with other mechanisms that might directly affect adult mortality irrespective of malaria incidence. For example, temperature variability might affect in utero health through the development of respiratory diseases or transmission of maternal insults from mental health or food insecurity for instance (Molina and Saldarriaga 2017). Another possible channel arises from the effects of temperatures that favor agricultural productivity, which might affect nutrition and agricultural income (Barreca 2010). Sugarcane, corn, and soy constitute the main agricultural crops in Brazil, with sugar and corn alone accounting for around 24.5 percent of the total agricultural production between 1965 and 2010.⁴⁸ Sugarcane ideal temperatures range from 22°C to 30°C, with growing season between January and March, whereas ideal temperatures for corn yields are from 25°C to 30°C and can be grown between the months of August and May.⁴⁹

To address the concern about the climatic confounding mechanisms raised above, I construct two additional sets of instruments: one that measures the proportion of the individual's in utero life in which monthly average temperatures are at least one standard deviation above yearly average temperature to capture the adverse health effects from extreme weather variations.⁵⁰ Next, I introduce temperature ideal instruments for both sugarcane and corn yields, as well as soy, as the proportion of the "growing season", in which monthly level average temperatures are between 22°C and 30°C, during sugar cane growing season, between 25°C and 30°C during corn growing season, and between 28°C and 32°C during soy growing season.

48. Data from Ministry of Agriculture and IBGE.

49. See <http://www.agencia.cnptia.embrapa.br/> (in Portuguese) for information on ideal temperatures for the crop yields and USDA Agricultural Weather Assessment (<https://www.usda.gov/oce/weather/pubs/Other/MWCACP/samerica.htm>) for information on their corresponding growing seasons. Accessed on 03/30/2019.

50. See Deschenes and Moretti (2009) and Barreca (2012) for discussions on the effects of extreme weather shocks in the United States.

Table B5 shows the estimated results for the alternative set of instruments described above.⁵¹ As one can observe, the effects are not statistically significant at any usual confidence levels for any of the outcomes. Importantly, the first stage F statistics for the joint significance of the excluded instruments are extremely small, suggesting a weak correlation between the constructed measure of exposure to malaria and climatic factors that are ideal to agricultural productivity. Indeed, the important factors explaining in utero exposure to malaria is the *joint* contribution of the specific biological and geographic factors that determine the strength and stability of malaria transmission across different environments, captured by the state-level short-term seasonal variations in temperature *and* precipitation.

B.6 Exploring Alternative Timing of Exposure

Throughout the analysis above, I assume full exposure for individuals born in 1959 and no exposure for individuals born in 1960. However, since timing of birth is a continuous variable, one might be skeptical about the choice of the year of 1959 to identify the pre-eradication birth cohort, as it is possible that the effects of the campaign have happened prior to that year. I might, therefore, be misclassifying individuals according to the degree of exposure. If that is the case, my results above would be capturing a different source of negative shock on early life exposure. Data limitations preclude an exact construction of exposed versus non-exposed cohorts, given the disparity in the frequency of the exposure (yearly) and individual-level birth dates observations (daily). Although I am not able to correctly identify individuals' exposure according to their exact timing of birth, the data allow me to test different ranges of birth dates for categorizing early life exposure. For instance, in one of the specifications I consider the (fully) exposed sample of those individuals born before the last quarter of 1959, which assures limited postnatal exposure in that year. The results for this specification suggest stronger and statistically significant treatment effect of early life exposure. Additionally, testing for different cohorts (such as 1961, 1962, etc.) as

51. Estimates are for the cohorts born prior to 1960 (between 1953 and 1959) to make sure that malaria was in fact prevalent.

the placebo group does not alter the main results of no treatment effects.⁵²

To ensure that the effects observed for the 1959 birth cohort (and for cohorts around that period) are indeed due to malaria exposure, I add older cohorts to the pre-eradication sample, given that the malaria burden before 1959 was likely to be more pronounced. By the same token, I add younger cohorts to the post-eradication sample to establish lower levels of exposure at the other end. In particular, I consider the joint effect of in utero exposure to malaria on those individuals born between 1953 and 1964. This particular choice of years covers the period in which malaria was endemic countrywide to being nearly eradicated in most parts of the country.⁵³ The estimation results, displayed in table B4, shows statistically significant treatment effects of exposure to malaria on years of education and primary completion for the different choices of birth cohort groups, suggesting that the main results are not likely to be driven by the specific choice of the birth year groups.⁵⁴

B.7 Endogenous Timing of Birth

The results of previous sections might also suffer from bias toward my estimates if households are able to systematically and endogenously choose the timing of gestation based on the seasonal risks of malaria infections. Although data limitations do not allow me to directly test whether the particular timing of birth is correlated with household characteristics (I do not observe mother’s information, for example), I analyze whether individuals’ sociodemographic characteristics are correlated with their own timing of birth.⁵⁵ I find no statistically

52. Results are available upon request.

53. The choice of cohorts in my analysis imposes an important trade-off: while introducing older cohorts ensures a significant difference of overall malaria exposure across treatment and control groups, the estimation might render less precise results and of difficult interpretation, as longer horizon comparisons might introduce biases from compositional effects because broader birth year ranges would likely be contaminated by changes in the socioeconomic environment. For example, in 1964, Brazil underwent a series of political events that led to a military coup d’État, which affected society in ways that would likely be correlated with the outcome variables in the analysis.

54. However, the results in this section should be taken with a grain of salt, given the potential biases introduced by the larger cohorts.

55. I essentially use individual level characteristics as *proxies* for parental background. This assumption is based on the fact that intergenerational transmission of wealth is extremely relevant and salient in the Brazilian context (Dunn 2007; Ferreira and Veloso 2006).

significant correlation between most of the individuals' characteristics and their month of birth, controlling for state-specific linear trends.⁵⁶ These findings, thus, provide no sufficiently robust evidence to support the claim that timing of birth is endogenously determined according to individual-level socioeconomic and demographic characteristics.

56. Results are available upon request.

Appendix C. The Stability of Malaria Transmission

Throughout the analysis above, I assume that the relative risk of malaria transmission is constant (or at least does not vary much). This assumption is necessary for identifying relative exposure levels across states and months of births, given the absence of incidence data for the period around the eradication era. In this section, I discuss the plausibility of the stability malaria transmission assumption as well as its shortcomings. If malaria relative transmission does not change over time, we should observe similar patterns over the time period in which monthly data is available. Figure C1 shows the monthly reported number of cases per capita across the period 2007-2017 in Brazil.

In general, January is the month in which malaria transmission rates are the largest. This high incidence coincides with the peak of the summer season, in which temperatures are well above average. Moreover, a second peak in transmission can be identified during the month of June, which coincides with the peak of the raining season in most regions of Brazil. The remaining months follow a similar pattern, with a relative decline both after January and June, and picking up as the year approaches December. The general trends are observed across different years, suggesting a potential stability in relative malaria transmission rates for different periods.

Two main factors might plausibly invalidate the assumption of constant relative malaria transmission: heterogeneous evolution of public health system efficiency across states and in individual-level prophylactic (and remedial) measures adopted by across both locations and time. If the evolution of malaria treatment and prevention did not evolve homogeneously across regions, the relative risk of transmission might have changed over time. Figure C2 addresses this potential issue by describing regional evolution of two important health sector components. Panel C2a displays how the number of public health facilities have evolved between 2005 and 2017, whereas panel C2b shows the decline in infant mortality between 1979 and 2017, across the four regions (North excluded) in Brazil.

Panel C2a exhibits a clear positive and parallel trend across different regions, which does not refute the hypothesis that the overall reduction in malaria transmission rates have happened in a proportional fashion. Provision of resources to control malaria is a task attributed to the central government, which transfers funds to the local authorities, who in their turn, use them on measures to prevent and treat malaria. It is relevant to notice an important characteristic of the Brazilian public sector: the distribution of the public resources transfers from the central government to states (and municipalities) is determined by the constitution, as to ensure equal regional development across different regions. Therefore, it is expected that local health institutions to have evolved in a similar manner. The observed regional trends, along with the institutional arrangements in Brazilian public sector spendings, then, alleviate the concern of heterogeneous efficiency of the health sector in controlling malaria over time.

Prophylactic measures – such as the use of bednets, mosquito repellents, avoidance of exposure to risky environments – and treatment measures – including intake of antimalarial drugs – might have evolved differently across different locations in Brazil since the time of the eradication era. Since one could expect such measures to correlate with improvements in the health status of the country as a whole, panel C2b uses regional infant mortality rates to proxy for these changes. The figure points out to a similar pattern as observed in the above panel: infant mortality seems to have been steadily declining uniformly across regions in Brazil. Taken together, the evidences provided in this section provide suggestive evidence in favor of the assumption that relative malaria transmission rates across locations are stable over time, reassuring the robust treatment effects estimated above.

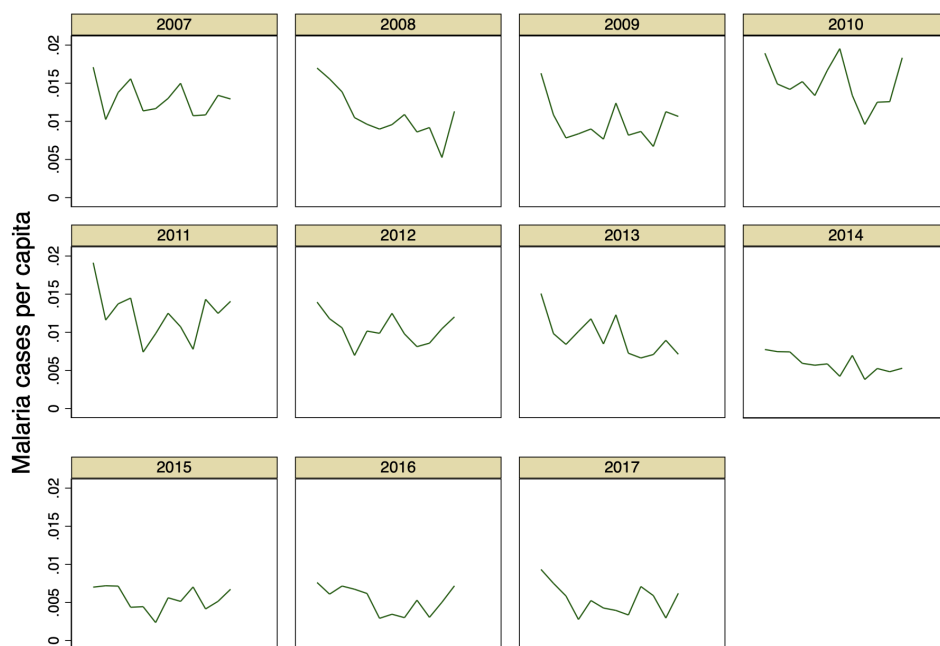

Despite the compelling plausibility of the assumption of stable relative malaria transmission over time, it is worth mentioning the implications for my results if this assumption is violated. First, suppose that wealthier regions were able to control malaria transmission rates disproportionately more efficiently than poorer ones. That is, although the constitutional fund enforces equitable allocation of resources, their utilization might have been

disproportionately more efficient in more developed regions. In this case, the malaria intensity measure used in the above analysis might in fact be underestimating the malaria burden in wealthier regions, rendering biased OLS estimates in favor of my results.⁵⁷ Suppose now that poorer regions were able to catch up with wealthier ones with respect to the use of the public resources. In this situation, the relative measure of malaria transmission would underestimate the prevailing malaria burden in poorer regions around the eradication era. The estimates above would, then, constitute a lower bound for the true treatment effect of in-utero exposure to malaria.

57. The Instrumental Variables approach might alleviate some of the potential measurement error bias, although the assumption of classical measurement error is likely to be violated in this situation.
